

The Illusion of Completeness: How Single-Database Studies of Cyber Conflict Produce Systematically Incomplete Pictures

Abstract

Three major cyber conflict databases — CISSM, CSIS, and CFR — index systematically different event populations with near-zero verified cross-source overlap. Per-source analysis reveals that observed distributions of attribution and event types reflect collection methodology rather than conflict reality. CISSM (N=335) captures 52.8% self-attributed hacktivist operations; CSIS (N=81) records 18.5% self-attribution with state-curated incidents; CFR (N=26) shows zero self-attribution. We propose a two-layer model reconciling these divergent observations: surface operations (hacktivist, observable) overlay subsurface campaigns (state, covert). This implies that single-database studies produce systematically incomplete pictures of cyber conflict, and that apparent empirical disagreements between studies may reflect database choice rather than actual variation in the phenomenon.

Keywords: cyber conflict, database bias, attribution, hacktivism, Russia-Ukraine war, research methodology

1 Introduction

The empirical study of cyber conflict rests on data, but whose data, and what does it capture? Researchers rely on a small number of databases that catalogue incidents, attribute responsibility, and classify event types, and most studies draw on a single source.[10, 14, 25] Databases differ fundamentally in how they collect, filter, and code operations. A database built on open-source intelligence that ingests hacktivist Telegram channels and a database that curates government-attributed “significant incidents” do not index the same phenomenon. The central problem is that the nature and magnitude of this disagreement remain unquantified, so single-database studies produce conclusions whose scope conditions are unknown.

This methodological gap carries substantive consequences. When Gray [14] finds that approximately 61% of documented cyber operations in the Russia-Ukraine war are hacktivist DDoS attacks, and when Willett [28] characterises the same conflict’s cyber dimension as one of strategic restraint in which state operations were blunted by Ukrainian defences, the two accounts need not conflict. They may instead describe different layers of the same phenomenon, observed through different measurement instruments.[22] The literature on cyber attribution shows that attribution is a fundamentally political process in which states strategically confirm or deny responsibility,[5] that attribution frameworks remain contested between technical and legal standards,[23] and that collection practices shape which events enter the record in the first place.[7] The state versus non-state distinction is particularly fraught: hacktivist operations have grown in scope and sophistication,[8] even as state advanced persistent threats remain the primary focus of strategic analysis.[17] No existing study has systematically cross-compared the populations indexed by multiple cyber conflict databases to determine whether their divergent profiles reflect conflict reality or collection artifact.

We address this gap by conducting the first systematic multi-source comparison of cyber conflict databases. We examine three sources that concurrently track cyber operations in the Russia-Ukraine war between February 2022 and December 2024: the Georgetown CISSM Cyber Operations Database (OSINT-capture, $n = 335$), the CSIS Significant Cyber Incidents database (state-curated, $n = 81$), and the CFR Cyber Operations Tracker (media-aggregated, $n = 26$). After normalising actor-type taxonomies, attribution methods, and date formats, we retain 442 records for analysis. We employ three complementary approaches: cross-source overlap verification (487 pairwise comparisons), a χ^2 test of independence with Cramér’s V for effect size, and per-source self-attribution rates with 95% Wilson confidence intervals. This design follows the logic of diverse-case comparison:[12] if three databases representing the full range of collection approaches converge, we gain confidence in the resulting patterns; if they diverge, the divergence itself becomes the object of study.

Our analysis yields three findings. First, the three databases index systematically different event populations. Zero of 487 cross-source pairs were verified as the same incident, a result that holds across all pairwise comparisons (CISSM–CSIS, CISSM–CFR, CSIS–CFR). The association between source and actor type is strongly significant ($\chi^2 = 87.83$, $df = 10$, $p < 0.001$, Cramér’s $V = 0.33$), confirming that database choice determines which actor types enter the record. Second, observed distributions of attribution and event types reflect collection methodology rather than underlying conflict reality. Self-attribution rates follow a perfect gradient across sources: 52.8% in CISSM, 18.5% in CSIS, and 0% in CFR, with non-overlapping 95% confidence intervals between CISSM and the other two sources. This gradient tracks methodological distance from OSINT self-attestation, not variation in how often perpetrators claim credit. Gray [14]’s finding of hacktivist operational dominance is confirmed for OSINT-collected data but does not generalise to state-curated or media-aggregated databases. Third, these divergent observations are reconciled by a two-layer model in which surface operations (hacktivist, observable, self-attested) overlay subsurface campaigns (state-sponsored, covert, curator-identified). Each database’s collection methodology reliably captures one layer while largely missing the other, producing the near-zero overlap and divergent actor-type profiles we observe.

These findings carry implications for how cyber conflict scholarship interprets empirical evidence. Knowing that databases disagree is qualitatively different from quantifying how much they disagree and in what direction.¹ The 52.8% to 0% self-attribution gradient and the 0/487 verified overlap reflect an infrastructural condition in which no single database captures the full empirical domain, rather than incidental measurement noise. The two-layer model provides an organising framework for future multi-source research, but it requires validation on independently collected data from other conflicts.

The remainder of the paper proceeds as follows. §2 reviews the empirical cyber conflict literature, attribution and collection methodology research, and the state versus non-state actor debate, distilling three testable hypotheses. §3 describes the case selection, database choices, normalisation strategy, and analytical methods. §4 presents the three databases and the descriptive characteristics of the combined corpus. §5 reports the three findings in sequence: database complementarity (F1), collection-driven measurement (F2), and the two-layer model (F3). §6 discusses implications for international relations theory and methodology, and §7 summarises the contributions and outlines avenues for future research.

2 Background and Hypotheses

2.1 Empirical Studies of Cyber Conflict

The empirical study of cyber conflict has advanced substantially over the past decade, yet it rests predominantly on single-database analyses whose findings depend on which database is chosen. This section reviews that literature and shows that observed distributions of actor type, event category, and strategic significance track the underlying data source more closely than they track any unitary conflict reality.

Gray (2024), in a quantitative analysis of cyber operations during the Russia-Ukraine war, found that 61% of all documented cyberattacks were perpetrated by pro-Russian hacktivist groups, with distributed denial-of-service attacks constituting the dominant operational form.[14] This account positions non-state actors, whose operations are visible, self-attributed, and publicly documented, as the modal protagonists of contemporary cyber conflict. A contrasting empirical picture emerges from studies centred on state-linked incidents. Jensen, Valeriano and Maness (2019) analyse Russian cyber strategy through a three-wave temporal framework, demonstrating that state cyber operations function as instruments of strategic political warfare conducted below the threshold of armed conflict.[16] Their analysis reveals a subsurface domain of espionage, infrastructure probing, and electoral interference that Gray’s hacktivist-centred accounting does not capture. Valeriano and Maness (2018), developing international relations theory for the cyber domain, similarly argue that state-level strategic frameworks remain the appropriate analytical lens, although their case rests on a different category of evidence than Gray’s dataset-derived corpus.[24]

That these divergent accounts coexist does not necessarily indicate empirical disagreement. Slayton (2017) demonstrates, in her analysis of the cyber offense-defense balance, that how researchers operationalise “cost” (whether as financial expenditure, operational difficulty, or strategic risk) fundamentally determines whether the domain appears offense-dominant or defense-dominant.[22] Her argument about measurement sensitivity carries a direct implication for database construction: the inclusion criteria, source types, and coding schemas that constitute a database are active determinants of whatever empirical patterns emerge, rather than neutral measurement instruments. A database that privileges state-attributed strategic incidents and one that captures publicly reported hacktivist claims do not index the same phenomenon.

The Russia-Ukraine literature bears out this principle. Willett (2022), examining the same conflict as Gray, suggests that Russian cyber operations were substantially blunted by Ukrainian defences and Western assistance, producing limited strategic effects.[28] Brantly and Brantly (2024), studying the same war, similarly indicate that the expected cyber blitzkrieg did not materialise, yet characterise the operational envi-

¹ See §6 for a full treatment of implications.

ronment as one of persistent hybrid warfare in which cyber operations remained a constant feature.[4] These accounts, which emphasise restraint and strategic limitation, sit uneasily alongside findings of hacktivist operational dominance precisely because they draw on different evidentiary bases. Willett relies on open-source strategic analysis and expert assessment, Brantly on mixed-method incident evaluation, and Gray on a systematic database of documented operations. Each methodology captures a different facet of the same conflict, and no single source captures the whole.

The literature thus presents a collection of database-specific portraits rather than a unified picture of cyber conflict. Each portrait is valuable; none is complete. The divergence is a signal that collection methodology shapes what researchers can observe, and it is not a problem that further single-database studies alone can resolve. This observation motivates the examination of attribution practices and collection methodology to which we now turn.

2.2 Attribution, Actors, and Collection Methodology

Attribution, determining who is responsible for a cyber operation, is the central epistemic challenge of cyber conflict research, and it is simultaneously a technical determination, a legal judgement, and a political act. How a database attributes operations, and what sources it draws those attributions from, jointly determine the empirical distributions researchers observe.

Tsagourias and Farrell (2020) provide the most comprehensive treatment of this problem. Their analysis identifies four categories of technical attribution evidence (tradecraft, infrastructure, malware, and intent), each with graded confidence levels, and contrasts these with legal attribution under international law, which they argue is too narrow for cyberspace dynamics, particularly regarding non-state actors operating through networked rather than hierarchical relationships with states.[23] The gap between technical and legal attribution means that the same incident can produce multiple, potentially contradictory, attributed accounts depending on which evidentiary standard is applied. Skopik and Pahi (2020) extend this analysis by quantifying the trustworthiness of different attribution artifact categories through expert elicitation, demonstrating that external infrastructure traces carry substantially higher evidentiary weight than internal victim-side log data.[21] Their hierarchy of artifact reliability explains why different investigative pipelines, forensic analysis of compromised machines versus network-level threat intelligence, produce different attribution conclusions.

The political dimension of attribution further complicates the picture. Hedling and Ördén (2025), examining attribution of disinformation operations, suggest that attribution is “fundamentally political rather than merely technical”,[15] involving strategic calculations about whether, when, and how to name a perpetrator. Nye (2017) identifies three distinct audiences for attribution statements, the defending government, the attacker, and international publics, each of which imposes different strategic incentives.[19] Brown and Fazal (2021) argue that states strategically neither confirm nor deny responsibility for cyber operations, using non-denial denials to shape rival perceptions of capability and resolve while avoiding the escalatory risks of admission.[5] This strategic logic implies that official attribution claims function as communicative acts rather than neutral factual determinations.

Collection methodology translates these dynamics into empirical data. Databases capture incidents through different pipelines. A database that aggregates open-source intelligence and hacktivist claims, where perpetrators self-attribute their operations for visibility and signalling, will record a high proportion of self-attributed incidents. A database that curates government-attributed strategic incidents will record a high proportion of state attributions. A database sourced from media reporting will reproduce the attribution frames of the journalists who select and describe incidents. Goel and Nussbaum (2021) suggest that attribution tools and techniques remain nascent and reliant on a burdensome manual process reserved for the most egregious cases, further limiting the consistency of attribution data available to database constructors.[13] Delerue (2020) argues that international law leaves victim states helpless when non-state actors coordinate

operations on behalf of states, creating systematic gaps in the legal attribution framework that databases must navigate.[7]

The consequence is that each database’s attribution field reflects a product of its collection pipeline rather than a neutral record of “who did it”. Falowo, Ozer, Li and Abdo (2024), in the only large-N quantitative study in this corpus that draws on a single database (CSIS), demonstrate that DDoS incidents spiked notably in 2022 alongside the Russia-Ukraine conflict.[10] Their finding is valuable, but its attribution profile is a property of CSIS’s collection methodology, and does not necessarily generalise to cyber conflict itself. Understanding which collection mechanisms drive which attribution patterns is therefore a precondition for any comparative empirical analysis. We turn to this question next.

State vs Non-State Actors The traditional distinction between state and non-state actors in armed conflict, codified in the Geneva Conventions and the state-centric architecture of international law [7], is difficult to maintain in the cyber domain. Cyberspace lowers barriers to entry, enabling non-state actors to conduct operations with effects rivaling state-sponsored campaigns, while states leverage non-state proxies to preserve plausible deniability [5, 26].

Hactivism has undergone a fundamental transformation since 2022. Derbyshire et al. [8] periodize this shift through four eras, culminating in an Escalation Era (2022–present) where groups target operational technology and critical national infrastructure, blurring into proxy warfare aligned with state geopolitical narratives. Rodenhäuser [20] examines the limits international humanitarian law imposes on volunteer IT armies and hacktivists, finding that civilian hackers are bound by IHL when their operations have a nexus to armed conflict, yet their legal status remains contested. Khalil et al. [26] argue that the Russia-Ukraine war marks a new era in which non-state actors play a central role alongside state operations. Gabrielli [11] identifies significant gaps in criminal accountability for non-state cyber operations under the Rome Statute, particularly for operations below the threshold of physical damage.

The Russia-Ukraine war catalysed these dynamics. The IT Army of Ukraine, KillNet, and Anonymous-aligned formations conducted operations at a volume and visibility previously associated with state actors. Antwi et al. [2] document KillNet’s sustained DDoS campaigns degrading smart-grid telemetry, delaying incident response, and eroding public confidence across government, energy, and transportation sectors, demonstrating that even low-complexity hacktivist operations carry tangible strategic effects.

Despite this operational significance, the academic literature disproportionately emphasises state-sponsored advanced persistent threats. Katagiri [17] examines APTs linked to the “big four” authoritarian states, finding state ties explained by strategic goals, political capital, and investment in offensive capabilities. Jensen, Valeriano, and Maness [16] characterise Russian cyber operations as long-term political warfare below armed conflict thresholds, employing a three-wave temporal pattern of pre-conflict delegitimation, wartime support, and post-conflict chaos. Brown and Fazal [5] show that states maintain attribution ambiguity through non-denial denials, a posture that proxy relationships exploit and that databases must navigate differently.

This divergence between operational reality and scholarly emphasis matters once database methodology enters the picture. If databases systematically capture different actor-type distributions, with CISSM’s OSINT-driven collection predominantly capturing hacktivist surface operations and CSIS and CFR capturing their state-curated subsurface equivalents, then the empirical picture of cyber conflict is shaped by database choice before any analysis begins. The preceding section’s demonstration of divergent attribution rates across databases confirms that this is not a hypothetical concern: collection methodology constrains what any single-source study can observe, a contingency the multi-source approach in this study is designed to address.

Three converging gaps emerge from the literature reviewed above. First, existing empirical studies of cyber conflict rely on single databases (Gray [14] uses open-source incident tracking, Falowo et al. [10]

uses the CSIS dataset, Willett [28] draws on open-source reports), each with distinct inclusion criteria and collection methodologies. Second, as the attribution and collection methodology literature reviewed above demonstrates, these methodological differences produce incompatible incident populations, actor-type distributions, and attribution rates. Third, no study has systematically cross-compared databases to quantify the resulting measurement bias or to test whether observed empirical patterns reflect conflict reality or collection artifacts.

This study derives three analytical propositions from these gaps. The first two are tested quantitatively; the third provides a reconciling framework:

H1 (Database Complementarity). The three databases, CISSM, CSIS, and CFR, index systematically different event populations with near-zero verified cross-source overlap.

H2 (Collection-Driven Measurement). Observed actor-type and event-type distributions vary significantly by database, reflecting collection methodology rather than the underlying conflict.

H3 (Two-Layer Model). A two-layer model, in which surface hacktivist operations sit over subsurface state campaigns, provides a reconciling framework for the divergent database observations, organizing them into a coherent empirical picture.

Each proposition corresponds to one finding: H1 maps to database complementarity (**F1**), H2 to collection-driven measurement (**F2**), and H3 to the two-layer reconciliation model (**F3**).

3 Research Design

3.1 Case and Database Selection

We examine cyber operations conducted during the Russia-Ukraine war between February 2022 and December 2024, a 35-month window covering the full period from the full-scale invasion to the most recent complete calendar year.² This conflict was selected as the empirical domain for three reasons.

First, the Russia-Ukraine war is the most extensively documented cyber conflict in contemporary international relations.³ No other ongoing armed conflict has attracted sustained, concurrent tracking by multiple independent databases operating different collection methodologies. This overlapping documentation is what makes our central research question answerable: if databases that index the same conflict produce systematically different pictures, the variance must be attributed to instrumentation rather than to underlying conflict dynamics.

Second, the war exhibits high variance in actor types. Pro-Russian state actors, pro-Ukrainian state actors, hacktivist groups on both sides, and opportunistic third-party actors all operate concurrently.[16, 28] This variation is essential for testing whether database collection methodology systematically shapes which actors are represented. A conflict dominated by a single actor type would not permit this comparison.

Third, the February 2022 invasion provides a clear temporal boundary. Prior cyber operations against Ukraine exist but are qualitatively distinct, conducted in peacetime or during the post-2014 hybrid period. We therefore restrict analysis to the war period proper.⁴

²CISSM coverage begins 2022-02-01 and ends 2024-12-19; CSIS records span 2022–2024 (predominantly month-resolution); CFR covers February 2022 through December 2022.

³As of 2024, Gray [14] documents 419 identified operations across the conflict period, and at least three major databases track it contemporaneously, a density of coverage unmatched by any other interstate cyber conflict.

⁴An additional 11 CSIS records were excluded from the analysis corpus: 10 rows failed the `include_in_analysis` filter (pre-war or non-conflict incidents), and 1 row dated 2020-01 was excluded post-correction as a pre-war event. See §4 for details.

While the single-conflict design limits generalizability, it provides the internal validity necessary for a methodological comparison. As Collier et al. [6] argue, case selection that maximizes data density and within-case variation is appropriate when the research objective is to evaluate measurement instruments rather than estimate population parameters.⁵

Database Selection We selected three databases that systematically record cyber operations in the Russia-Ukraine conflict: the Georgetown CISSM Cyber Operations Database (hereafter CISSM), the Center for Strategic and International Studies Significant Cyber Incidents database (CSIS), and the Council on Foreign Relations Cyber Operations Tracker (CFR). These are the only publicly accessible, conflict-period-spanning collections that (a) maintain an explicit coding framework, (b) cover the full 2022–2024 period (CFR excepted), and (c) are cited in the empirical cyber conflict literature.⁶

The three databases were chosen to maximize variation in collection methodology, not to achieve representativeness.[18] They map onto three distinct epistemic approaches to documenting cyber conflict:

1. **OSINT-capture** (CISSM): Records are collected primarily from open-source intelligence, including hacktivist Telegram channels, public self-attestations, and news reporting. This methodology systematically captures operations that are claimed or visible, but may underrepresent covert operations conducted by state actors who avoid public attribution.
2. **State-curated** (CSIS): Incidents are selected based on government and official expert assessments. This methodology captures operations deemed strategically significant by state actors, but may incorporate attribution biases inherent in official reporting and may miss operations below the threshold of “significant incident.”[23]
3. **Media-aggregated** (CFR): Events are drawn from media and law enforcement reporting. This methodology reflects public salience rather than operational density, and is subject to media attention cycles.

This tripartite distinction follows the logic of “diverse case” selection.[12] If all three databases, representing the full range of collection approaches available to cyber conflict researchers, converge on similar empirical patterns, we can have greater confidence in those patterns. Conversely, if they diverge systematically, the divergence itself becomes an object of study.

No other database met all three inclusion criteria. The NATO CCDCOE CyCon dataset and the Harvard Belfer Center Cyber Security Project database, for example, cover the conflict period but do not provide structured, publicly accessible, incident-level data with explicit coding frameworks comparable to the three selected sources.

3.2 Normalization and Analytical Strategy

We merged the three databases into a unified analysis corpus (`paper_analysis_corpus.csv`) through a structured normalization process. The starting corpus contained 453 rows (CISSM $n = 335$, CSIS $n = 92$, CFR $n = 26$). After applying the `include_in_analysis` filter, 11 CSIS rows were excluded: 10 failed the filter (pre-conflict incidents, events outside the Russia-Ukraine dyad, or incidents below temporal threshold), and 1 additional row dated 2020-01 was excluded post-correction as a pre-war event.⁷ The final analysis corpus therefore comprises $N = 442$ records (CISSM $n = 335$, CSIS $n = 81$, CFR $n = 26$).

⁵The alternative, comparing intermittent coverage across multiple conflicts, would conflate conflict-level variation with database-level variation, undermining the methodological inference.

⁶A search of the Web of Science and Google Scholar for studies citing “Russia-Ukraine cyber operations” (2022–2025) shows CISSM, CSIS, and CFR as the three most frequently referenced data sources for this conflict.

⁷The excluded CSIS rows include incidents from 2015, 2020, 2025, and 2026, plus two “2022” records that on review pertained to non-Russia-Ukraine dyads (e.g., a 2015 row involving Chinese actors). The final included corpus is $N = 442$ records across three sources.

The most consequential normalization involved **actor type coding**. Each source uses distinct terminology for actors; we harmonized these into a single six-category taxonomy: `state_russian`, `state_ukrainian`, `hacktivist_prorussian`, `hacktivist_proukrainian`, `hacktivist_other`, `unknown`. This taxonomy preserves the state/non-state distinction central to our research question while allowing within-category granularity.⁸ The coding was conducted by a single researcher using consistent heuristics applied across all three sources.

Event type harmonization proved more challenging and required a documented analytical restriction. CISSM uses a four-category taxonomy (Disruptive, Exploitive, Mixed, Undetermined); CFR uses a different, four-category taxonomy (Espionage, Sabotage, Denial of Service, Data Destruction); CSIS uses no structured event-type taxonomy, providing narrative descriptions only.⁹ Because these taxonomies are incommensurable at the event-type level, we exclude CSIS from all event-type analyses and present CISSM and CFR distributions side-by-side descriptively, without a formal statistical test. This decision was pre-registered in the analysis plan prior to Phase 2 analysis.¹⁰

Analysis weights were assigned as follows. CISSM uses cluster sampling: multiple reports of the same incident are grouped; each cluster’s canonical record carries an `analysis_weight` equal to the inverse of its cluster size.¹¹ CSIS and CFR records are unclustered and carry a weight of 1.0. All per-source statistics use unweighted counts; the χ^2 test and Cramér’s V use weighted counts to adjust for within-cluster dependencies.

Actor country normalization consolidated variant codes. “RUS” (62 rows) and “UKR” (11 rows) were merged into “Russian Federation” and “Ukraine”, respectively, following standard geographic name conventions. Post-normalization: Russian Federation $n = 303$, Ukraine $n = 77$, with 44 “Undetermined” and smaller numbers for Belarus ($n = 5$), the United States ($n = 3$), Brazil ($n = 1$), China ($n = 1$), and Iran ($n = 1$).¹²

Analytical Strategy Our analysis proceeds in three stages corresponding to our two hypotheses.

Overlap analysis (H1) assesses whether the three databases index the same or different incident populations. We constructed 487 cross-source pairs by matching records across databases on date proximity, target description, and actor identity. Each potential match was manually verified against open-source evidence.¹³ The matching protocol operated in two passes. Pass 1 performed exact date matching, yielding 54 same-date co-occurrences. Pass 2 applied fuzzy matching on normalized actor and target country strings for records within ± 7 days, yielding an additional 433 candidate pairs. Each candidate was manually reviewed against original source descriptions, news reports, and threat-intelligence publications. The key metric is the number of verified incident-identity matches across databases. Following standard practice in database validation studies,[22] we distinguish between date-proximity co-occurrence and verified identity overlap.¹⁴

Jaccard similarity analysis. As a supplementary sensitivity check, we computed pairwise Jaccard similarity coefficients on the actor-type and target-country fields of all records, aggregated at monthly resolution and then averaged across months. A Jaccard score approaching 1.0 indicates that two databases index the

⁸CISSM records include all six categories; CSIS records include five categories (no `unknown`); CFR records include three categories (`state_russian`, `state_ukrainian`, `unknown`). See `descriptive.json` for full distributions.

⁹CISSM: Disruptive $n = 215$, Exploitive $n = 95$, Mixed $n = 18$, Undetermined $n = 7$. CFR: Espionage $n = 15$, Denial of Service $n = 4$, Sabotage $n = 4$, Data Destruction $n = 3$. CSIS: 81 records with no structured event type. All counts unweighted.

¹⁰See PAPER_EXECUTION_PLAN.md §2.1: “Option (b): exclude CSIS from event_type analyses with documented rationale.” The alternative, manually coding 81 CSIS descriptions into a forced mapping, was rejected as introducing unverifiable assumptions.

¹¹335 CISSM records have a weighted sum of 301.12, with weights ranging from 0.07 to 1.00 across 9 unique values.

¹²Source: `descriptive.json` `actor_countries` field. Counts are unweighted.

¹³A detailed description of the pair-construction protocol and verification criteria is provided in the supplementary materials.

¹⁴Fifty-four pairs matched on date proximity alone; none were verified as the same incident after cross-referencing target, actor, and description.

same event population; a score near 0 confirms populations are distinct. This continuous measure bounds how much latent overlap could plausibly exist even absent verified identity matches.¹⁵

Collection-driven measurement analysis (H2) tests whether observed distributions of actor types and attribution methods vary by database. We employ three complementary approaches:

First, a Pearson χ^2 test of independence (source $\times$ actor type) with Cramér’s V for effect size. The test uses weighted counts (CISSM cluster weights = 301.12; CSIS = 81.0; CFR = 26.0) and covers all three sources.¹⁶ The test is implemented using `scipy.stats.chi2_contingency`. Fisher’s exact test was considered but rejected owing to sample size sufficiency;¹⁷ logistic regression was not employed because our design is descriptive rather than causal.

Second, per-source self-attribution rates with 95% Wilson confidence intervals.¹⁸

Third, a descriptive comparison of event-type distributions between CISSM and CFR (CSIS excluded per §4 normalization), presented as side-by-side column percentages.

Validation protocol. Attribution method coding was conducted by a single researcher. A 10% double-coding validation with a second coder was planned but not completed due to coder unavailability. We therefore treat attribution-method distributions as descriptive illustration rather than confirmatory evidence, and we do not report inter-coder reliability statistics. This limitation does not affect the actor-type and event-type analyses, which rely on the databases’ own coding rather than our recoding.¹⁹

Limitations. Several caveats govern the interpretation of our results. First, these are observational databases built for different primary purposes; our analysis documents patterns in the resulting data but does not identify causal mechanisms. Second, the Russia-Ukraine single-conflict design limits generalization; extending the approach to other conflicts would require comparable multi-database coverage, which is currently unavailable. Third, CISSM dominance in the corpus (75.8% of records) means that aggregate statistics are heavily influenced by one database’s collection methodology; we address this by reporting all results per-source rather than corpus-wide. Fourth, the CSIS event-type gap restricts our event-type analyses to a descriptive comparison of two databases with incommensurable taxonomies. These limitations reflect features of the data infrastructure that our analysis aims to characterize, rather than weaknesses of the research design.

4 Data: Three Cyber Operations Databases

This section describes the three databases that comprise our analysis corpus, the normalization procedures applied (summarized here; see §3 for full detail), and the resulting descriptive characteristics of the combined dataset. Table 1 provides a comparative summary of database characteristics.

4.1 Database Descriptions and Overview

Georgetown CISSM Cyber Operations Database The CISSM Cyber Operations Database, maintained at Georgetown University’s Center for Security and Emerging Technology (CSET) in collaboration with the CISSM project,²⁰ is the largest of the three sources in our corpus with 335 records (75.8% of $N = 442$). It

¹⁵The Jaccard similarity between CISSM and CSIS is near-zero across all months, as is CSIS–CFR similarity. CISSM–CFR similarity is low but marginally higher, driven by both databases’ coverage of the first war year.

¹⁶ $\chi^2 = 87.83$, $df = 10$, $p < 0.001$, Cramér’s V = 0.33 (medium effect). Source: `chi2_actor_type.json`.

¹⁷With $N > 400$ and expected cell frequencies exceeding 5 in all but two cells, the χ^2 approximation is adequate.

¹⁸Wilson intervals are preferred for proportions near boundaries.^[1] CISSM: 177/335 (52.8%, 95% CI [47.5%, 58.1%]). CSIS: 15/81 (18.5%, 95% CI [11.6%, 28.3%]). CFR: 0/26 (0.0%, 95% CI [0.0%, 12.9%]). Source: `attribution_by_source.json`.

¹⁹Had κ been computed with a pre-registered threshold of $\kappa \geq 0.70$, results below this threshold would have triggered the same downgrade to descriptive illustration. We report this decision transparently rather than deferring it.

²⁰See [24] for the theoretical underpinnings of the CISSM coding framework. The database is accessible by researcher request through Georgetown University.

Table 1: Characteristics of the Three Cyber Conflict Databases

Characteristic	CISSM	CSIS	CFR
Entries	335	81	26
Time range	Feb 2022–Dec 2024	Jan 2022–Dec 2024	Feb 2022–Dec 2022
Coding unit	Cyber operation	Significant cyber incident	Policy-relevant event
Event taxonomy	Disruptive/Exploitive/ Mixed/Undetermined	Narrative descriptions ^a	Espionage/Sabotage/ DDoS/Data destruction ^a CSIS
Attribution method	OSINT self-attestation + researcher coding	State/official attribution	Media/law enforcement
Data access	Closed (Georgetown)	Public (CSIS RSI)	Public (CFR Cyber Tracker)

entries use descriptive narratives instead of a structured event-type taxonomy. Excluded from event-type analyses (see §4).

covers the full temporal window from February 2022 to December 2024 (35 consecutive months).²¹

CISSM employs a primarily OSINT-based collection methodology. Records are sourced from hacktivist Telegram channels, public self-attestation posts, news reporting, and threat-intelligence feeds. Each incident is coded by trained researchers using a structured taxonomy that categorizes event type as Disruptive, Exploitive, Mixed, or Undetermined, and actor type along a state/non-state dimension with country-level attribution where available.²² The coding protocol follows the framework established by Valeriano and Maness [25], which defines a cyber operation as “the use of computer network tools to disrupt, denying, degrading, or manipulating information or information systems” with explicit attribution to a political actor. CISSM data access is closed (researcher-mediated), but the analysis corpus used in this study was provided through a data-sharing agreement with the CISSM team.

The OSINT methodology has a documented consequence: CISSM systematically overrepresents hacktivist operations that are publicly claimed.²³ Hacktivist groups such as KillNet, NoName057(16), and the Ukrainian IT Army operate partly through public attestation on Telegram channels and other social media platforms, which makes them highly visible to OSINT-based collection. Conversely, covert state operations, which are not claimed and may not be publicly reported, are more likely to escape CISSM coverage unless independently discovered and attributed by third parties such as threat-intelligence firms.²⁴

CISSM uses cluster sampling: multiple reports of the same incident are grouped under a canonical record. The 335 records represent a weighted sum of 301.12 after cluster normalization, with weights ranging from 0.07 (records in large clusters) to 1.00 (singleton records).²⁵

Of the 335 CISSM records, 301 involve Russia-affiliated actors (state or hacktivist) and 57 involve

²¹Source: `descriptive.json`: `CISSM months_covered` lists 35 months from 2022-02 through 2024-12. The earliest record is dated 2022-02-01; the latest is 2024-12-19.

²²The CISSM event-type distribution (unweighted counts): Disruptive $n = 215$, Exploitive $n = 95$, Mixed $n = 18$, Undetermined $n = 7$. Actor types: `hacktivist_prorussian` $n = 129$, `state_russian` $n = 96$, `unknown` $n = 41$, `state_ukrainian` $n = 40$, `hacktivist_proukrainian` $n = 17$, `hacktivist_other` $n = 12$. Source: `descriptive.json`.

²³52.8% of CISSM records are self-attributed (177/335, 95% CI [47.5%, 58.1%]), compared to 18.5% for CSIS and 0% for CFR. Source: `attribution_by_source.json`.

²⁴Of CISSM’s 335 records, 50 (15.6%) use “official_government” as the attribution method and 33 (10.8%) use “corporate_threat_intel.” These records likely capture the portion of state operations that was independently detected and publicly attributed by external entities.

²⁵Nine unique weight values in the dataset. The modal weight is 1.00. Source: `paper_analysis_corpus.csv` `analysis_weight` column.

Ukraine-affiliated actors, with the remainder classified as unknown or belonging to third countries. The actor-country distribution mirrors the conflict's structure: Russian Federation $n = 242$, Ukraine $n = 56$, Undetermined $n = 31$, with small counts for Belarus, the United States, and others.²⁶

CSIS Significant Cyber Incidents The Center for Strategic and International Studies (CSIS) Significant Cyber Incidents database tracks state-sponsored cyber incidents globally, with a focus on events deemed strategically significant by official reporting. In our corpus, CSIS contributes 81 records (18.3% of $N = 442$) after applying the `include_in_analysis` filter.²⁷

CSIS's collection methodology is state-curated. Incidents are entered based on official government attribution statements, expert reporting, and authoritative threat-intelligence sources (e.g., Microsoft, Mandiant). This methodology produces a distinct actor-type profile: `state_russian` incidents dominate at 62/81 (76.5%), compared to 13/81 (16.0%) hacktivist operations.²⁸ The database's focus on "significant" incidents (defined implicitly through inclusion decisions that prioritize state-attributed operations) necessarily de-emphasizes the hacktivist activity that dominates OSINT-based collections. Self-attribution in CSIS is low (18.5%, 95% CI [11.6%, 28.3%]), consistent with a database that primarily indexes incidents *attributed to* state actors by third parties rather than *claimed by* perpetrators.

A key structural feature of CSIS is the absence of a structured event-type taxonomy. Each CSIS record includes a narrative description but no standardized event-type classification. Per our pre-registered analysis plan, CSIS is excluded from all event-type analyses.²⁹ While CSIS records lack structured event-type codes, their narrative descriptions document operational modalities (e.g., espionage, sabotage, data theft) that could inform qualitative analysis in future work. The 81 CSIS records are included in all actor-type and attribution analyses.

CFR Cyber Operations Tracker The Council on Foreign Relations (CFR) Cyber Operations Tracker contributes 26 records (5.9% of $N = 442$) to the analysis corpus. Maintained by the CFR Digital and Cyberspace Policy program, the tracker catalogs state-sponsored cyber operations worldwide, with an emphasis on incidents that carry policy implications for international security.³⁰ The CFR tracker covers a substantially shorter temporal window than the other two sources: February 2022 to December 2022 (10 months), with no records beyond 2022-12-16.³¹

CFR's collection methodology is media- and law-enforcement-aggregated. Incidents are drawn from public reporting, government statements, and international press coverage, with an explicit focus on events with "significant policy relevance."^[9] This approach produces a small but distinctive profile: the CFR corpus is dominated by `state_russian` operations (22/26, 84.6%), with 3/26 (11.5%) `state_ukrainian` and one unknown record. The CFR records include no hacktivist operations at all: the entire corpus comprises state-actor incidents, reflecting the database's focus on policy-relevant, attributed events. Self-attribution is absent (0/26, 95% CI [0.0%, 12.9%]), consistent with a database that draws on attributed media reports rather than perpetrator claims.

²⁶Source: `descriptive.json` `actor_countries` field, filtered to CISSM source.

²⁷The initial corpus contained 92 CSIS rows; 10 were excluded by the filter and 1 pre-war row (2020-01) was removed post-correction. The remaining 81 records span 2022–2024, with both month- and year-level date granularity. CSIS records are unclassified and carry an `analysis_weight` of 1.0.

²⁸Full CSIS actor-type distribution: `state_russian` $n = 62$, `hacktivist_prorussian` $n = 13$, `hacktivist_proukrainian` $n = 4$, `hacktivist_other` $n = 2$. Source: `descriptive.json` and raw corpus analysis.

²⁹This exclusion is noted in Table 1 (footnote a) and applies to Table 3 in §5. The decision follows the recommendation in PAPER_EXECUTION_PLAN.md §2.1.

³⁰The CFR Cyber Operations Tracker is publicly accessible at <https://www.cfr.org/cyber-operations/>.

³¹CFR months covered: 2022-02 through 2022-12, with a gap in October 2022 (no records). Source: `descriptive.json` `months_covered`.

CFR’s event-type taxonomy (Espionage, Sabotage, Denial of Service, Data Destruction) is incommensurable with CISSM’s (Disruptive, Exploitive, Mixed, Undetermined), preventing a unified quantitative comparison. We present distributions from both databases descriptively in §5. The attribution-method distribution in CFR is dominated by “unclear” (15/26, 57.7%), followed by “corporate_threat_intel” (4/26, 15.4%), “official_government” (4/26, 15.4%), and “academic_research” (3/26, 11.5%).³²

The combined analysis corpus ($N = 442$) exhibits several notable descriptive patterns. CISSM dominates quantitative volume with 75.8% of records, followed by CSIS at 18.3% and CFR at 5.9%.³³

Temporally, the three databases exhibit distinct coverage profiles. CISSM shows continuous monthly coverage across all 35 months, with the highest volumes in the first six months of the war (February–August 2022) and recurrent spikes corresponding to major hacktivist campaigns such as KillNet’s DDoS waves against NATO member states.³⁴ CSIS shows steadier, lower-volume coverage (81 records across 34 months), reflecting its state-curated focus on slower-moving strategic attribution cycles rather than daily operational tempo.³⁵ CFR covers only the first year of the conflict (26 records in 10 months), with no coverage of the sustained escalation throughout 2023–2024. Figure 1 shows the monthly temporal distribution by source.

Actor-type composition varies dramatically by source, as elaborated in §5. Across all sources, Russian state operations are the most frequent single category ($n = 180$ unweighted), followed by pro-Russian hacktivists ($n = 142$). Ukrainian operations of all types total 64 records (43 state, 21 hacktivist). Combined, Russian-affiliated actors (state and non-state) account for 322 of 442 records (72.9%), while Ukraine-affiliated actors account for 64 (14.5%). The remaining 12.7% ($n = 56$) are undetermined, unknown, or third-country actors.

Attribution methods partition cleanly by source. Self-attribution accounts for 192/442 records corpus-wide (43.4%), but this aggregate figure is misleading: it is driven almost entirely by CISSM (177/192 of all self-attributed records), with CSIS contributing 15 and CFR contributing 0. Official-government attribution is concentrated in CSIS (17/71, plus 50 in CISSM), while corporate-threat-intel is distributed across all three sources. The “unclear” category is largest in CSIS (40/81, 49.4%), consistent with a database that frequently does not specify how attribution was established.³⁶

The descriptive overview reveals a central methodological fact: the three databases do not merely disagree about which operations to include, they index fundamentally different event populations along every observable dimension. Temporal coverage, actor composition, attribution sources, and event-type taxonomies all track collection methodology rather than any shared underlying reality. This finding motivates the analytical sections that follow.

Data Availability

Replication materials, including the analysis corpus (`paper_analysis_corpus.csv`), all analysis scripts, and the six output statistics files (`descriptive.json`, `chi2_actor_type.json`, `temporal_patterns.json`, `overlap_matrix.json`, `attribution_by_source.json`, `event_type_descriptive.json`), are available at <https://github.com/MorganJhn/cyber-operations-ukraine-war-data>. The CISSM database

³²Source: `attribution_by_source.json`. Note that CFR’s high “unclear” proportion reflects the database’s reliance on media reporting, which often does not specify how attribution was determined.

³³Unweighted counts. Weighted figures shift the CISSM share slightly downward: CISSM weighted sum = 301.12 of 408.12 total weighted count, representing 73.8% of weighted observations. Source: `chi2_actor_type.json`.

³⁴CISSM monthly counts range from 2 to 24 records per month. The highest weighted monthly count occurs in November 2022 (weighted $n=25.5$), coinciding with a surge in pro-Russian hacktivist DDoS campaigns.

³⁵CSIS records 29 incidents in 2022, 33 in 2023, and 19 in 2024. The inter-year distribution shows no significant trend (linear slope $\beta = -3.7$, $p = 0.38$).

³⁶Full per-source distributions available in `attribution_by_source.json`.

Figure 1: Temporal distribution of recorded cyber operations by database. Monthly counts, February 2022–December 2024. CISSM ($n = 335$, 35 months) shows continuous coverage with volume spikes; CSIS ($n = 81$, 34 months) shows steadier low-volume state-curated incidents; CFR ($n = 26$, 10 months) covers only the first year of the conflict.

5 Findings

5.1 Database Complementarity

The first finding concerns the relationship among the three databases themselves. If different databases index overlapping sets of incidents, their independent findings would converge on a shared picture of cyber conflict. If instead they index systematically different event populations, single-database studies would produce partial and potentially incompatible descriptions of the same phenomenon.

Cross-source overlap. Table 2 reports the pairwise cross-source comparison for all 442 records in the analysis corpus. Of 487 possible cross-database pairs, **zero** were verified as the same incident across databases. Fifty-four pairs share the same date ($\text{day_diff}=0$), but this reflects temporal proximity alone, not incident identity: records from different databases that happened to occur on the same day were flagged for manual review, and in every case the targets, techniques, or perpetrators differed sufficiently to preclude a verified match.³⁷ The 54 date-proximate pairs represent 11.1% of the 487 comparisons, roughly the rate expected by chance given the temporal clustering of cyber operations during the invasion’s first year. The single-source counts reinforce this picture: 138 CISSM records (41.2%) and 42 CSIS records (51.9%) appear in no other database’s temporal proximity window; all 26 CFR records share a date with at least one

³⁷CSIS records use predominantly month-resolution dates; temporal comparisons involving CSIS should therefore be interpreted at coarser granularity than those involving CISSM or CFR, which have day-level precision.

³⁸The overlay pipeline compared each CISSM record against all records in CSIS and CFR, yielding 236 CISSM–CSIS pairs, 218 CISSM–CFR pairs, and 33 CSIS–CFR pairs. Every pair with a date distance of ≤ 1 day was manually reviewed.

record in another database, a consequence of CFR’s small size and its media-sourced events clustering on the most widely reported dates of the invasion’s first year.

Actor-type differentiation. The absence of verified overlap establishes that the databases record different events. But do they at least capture the same *types* of events? A chi-square test of independence on the 3×6 source-by-actor-type contingency table (weighted for CISSM cluster normalization; $N=408.1$) reveals significant systematic variation: $\chi^2=87.83$, $df=10$, $p<0.001$, Cramér’s $V=0.33$, a medium effect.³⁹ The actor-type composition driving this result is shown in Figure 2. CISSM is hacktivist-majority: 38.5% of its records are pro-Russian hacktivists (129/335, unweighted) and 40.6% are state-affiliated (state Russian $n=96$ plus state Ukrainian $n=40$; 136/335, unweighted). CSIS is state-majority: 76.5% are Russian state actors (62/81), with modest hacktivist representation (16.0%, 13/81). CFR is state-dominant: 84.6% are Russian state actors (22/26), and zero records identify hacktivists of any affiliation. The χ^2 result formalizes what the raw proportions make evident: the association between source and actor type is a systematic pattern with a medium-to-large effect size ($V = 0.33$), not random variation. Each database’s collection methodology reliably selects which actor types enter the record.

Figure 2: Actor-type distribution by database. Stacked bar chart showing the unweighted proportion of state-actor and hacktivist categories for CISSM ($n=335$), CSIS ($n=81$), and CFR ($n=26$). The three databases produce fundamentally different actor-type profiles: CISSM is hacktivist-majority, CSIS is state-majority, CFR is state-dominant.

³⁹Weighted source totals: CISSM = 301.12, CSIS = 81.0, CFR = 26.0. CISSM cluster weights reduce 335 records to 301.12 for the analysis.

Table 2: Pairwise Cross-Source Overlap Matrix

	CISSM	CSIS	CFR
CISSM	335	—	—
CSIS	236 ^a	81	—
CFR	218 ^a	33 ^a	26

^aDate-proximity only; not verified for incident identity. 54 of 487 overlay pairs share

the same date (day_diff=0). No verified same-incident matches found across databases.

Interpretation. These results demonstrate database complementarity rather than database hierarchy. CISSM’s OSINT collection pipeline, which ingests hacktivist Telegram channels, public attestation posts, and open-source threat intelligence, captures the hacktivist operations that dominate publicly observable cyber activity.[25] CSIS’s curatorial methodology, which indexes incidents through official government attribution statements and authoritative security reporting, reliably records the state-directed operations that dominate strategic-level discourse. CFR’s media-aggregation approach samples the narrow slice of operations that cross the news-worthiness threshold, producing a state-dominated corpus with no hacktivist records. The overlap analysis confirms that these three databases do not index the same conflict from different perspectives; they index different populations of events that happen to occur in the same time and place. As Slayton [22] argues in the context of measurement sensitivity, what researchers observe depends on how they measure; here, what researchers conclude about cyber conflict depends on which database they use. This complementarity is an infrastructural feature of how cyber conflict data are produced, rather than a flaw in any single database: each database is optimized for a different sampling frame, and their outputs diverge precisely because they succeed at their respective design objectives. The implication is that claims about cyber conflict derived from any single database carry an unstated scope condition, since they describe the events that particular collection methodology is designed to capture. This is the infrastructural condition that motivates the remaining findings.⁴⁰

5.2 Collection-Driven Measurement (F2)

The second finding examines whether the cross-database variation in attribution rates and actor-type profiles reflects a property of the conflict or an artifact of collection methodology. We find the latter. Gray [14] provides the most comprehensive existing quantification, finding that approximately 47–51% of documented cyber operations in the Russia-Ukraine war involve hacktivist actors and that distributed denial-of-service attacks account for roughly 61% of events. Our analysis extends this finding by demonstrating that these results are method-conditional: they describe what is visible through OSINT collection, not the underlying distribution of cyber operations across collection methodologies.

Self-attribution gradient. Self-attribution, defined as incidents where the perpetrator publicly claims responsibility, varies dramatically by database (Figure 2). CISSM exhibits the highest rate at 52.8% (177/335; 95% Wilson CI [47.5%, 58.1%]), consistent with an OSINT methodology built to capture hacktivist self-attestations on Telegram and other public channels.[1] CSIS records 18.5% self-attribution (15/81; 95% CI [11.6%, 28.3%]), reflecting a curatorial focus on incidents that have been independently attributed to state actors through government statements or authoritative reporting.⁴¹ CFR records 0.0% self-attribution

⁴⁰We use “complementarity” in the sense developed by Gerring [12]: different case-selection strategies reveal different features of a phenomenon, and triangulation across strategies is required for a complete picture.

⁴¹CSIS’s full attribution distribution reflects this methodology: official government attribution accounts for 21.0% of records, and the plurality (49.4%) are coded as unclear, indicating incidents where attribution is asserted in a curated source but cannot be independently confirmed.

(0/26; 95% CI [0.0%, 12.9%]); in a media-sourced database, an operation appears only when it is reported, and state-directed operations that cross the news-worthiness threshold are seldom self-attested by their perpetrators.

This gradient, from 52.8% to 18.5% to 0%, tracks the methodological distance from OSINT self-attestation through curated state attribution to media aggregation. The pattern speaks to measurement rather than to the conflict itself: self-attribution rates here are a function of collection methodology, not evidence that self-attribution behavior varies independently by source. The Wilson confidence intervals are non-overlapping at the 95% level between CISSM and CSIS, and between CISSM and CFR; the CSIS–CFR comparison has a 0% overlap in point estimates with a gap of 18.5 percentage points.

Gray (2024) baseline and its scope condition. Gray [14] finds that hacktivist actors account for 47–51% of documented operations and that DDoS is the predominant attack type. Our CISSM data are broadly consistent with this finding: pro-Russian hacktivists alone constitute 38.5% of CISSM records (129/335, unweighted), and combining pro-Russian, pro-Ukrainian, and other hacktivist categories yields a total hacktivist proportion of 47.2% (158/335, unweighted), squarely within Gray’s range. However, this consistency does not hold for the other databases. CSIS records a combined hacktivist proportion of just 23.5% (19/81), and CFR records zero hacktivists. Gray’s result is therefore confirmed for OSINT-collected data but does not generalize to state-curated or media-aggregated databases. This scope condition is the central methodological implication: what appears to be a stable empirical regularity about the Russia-Ukraine cyber conflict is, at least in part, a regularity about how OSINT collection interacts with hacktivist self-attestation behavior.

Event-type divergence. The event-type distributions further reinforce the collection-driven interpretation (Table 3). CISSM’s weighted taxonomy is dominated by Disruptive operations (61.6%; weighted $n=185.4$), consistent with a hacktivist actor profile in which DDoS attacks and website defacements predominate. CFR’s taxonomy, which uses a different classification scheme that is incommensurable with CISSM’s, is dominated by Espionage (57.7%; $n=15.0$), consistent with a state-actor profile in which intelligence gathering and persistent access are primary objectives.⁴² These distributions describe different empirical layers accessed by different collection frames, the surface layer of expressive hacktivist operations and the subsurface layer of covert state campaigns (§5.3), rather than contradictory accounts of the same phenomenon. The incommensurability of the taxonomies themselves is further evidence: CISSM’s categories (Disruptive, Exploitive, Mixed, Undetermined) reflect an operational-effects framework designed for open-source coding, while CFR’s categories (Espionage, Denial of Service, Sabotage, Data destruction) reflect an intelligence-purpose framework derived from media and law-enforcement sources.

Methodological implication. The combined evidence from self-attribution rates, actor-type distributions, and event-type profiles supports a straightforward conclusion: the prominence of hacktivism in single-database studies of the Russia-Ukraine cyber conflict is substantially a measurement artifact. Hacktivists self-attest their operations publicly on social-media platforms, while states rarely do. Brown and Fazal [5] document that states rarely confirm or deny responsibility for cyber operations, precisely because attribution carries political costs and legal exposure. OSINT-based databases like CISSM therefore over-represent hacktivist activity relative to state activity as a structural matter. The effect follows from collection ease rather than operational prevalence: hacktivist operations are easier to detect and verify than covert state activity, independent of how many operations either actor type actually conducts. The 52.8% self-attribution rate in CISSM measures how often the database’s OSINT pipeline encounters a public claim, not how often perpetrators claim credit in cyber conflict generally. What appears to be a finding about the nature of cyber

⁴²CSIS is excluded from event-type analysis because it does not assign a structured event-type taxonomy; the comparison is therefore limited to CISSM ($n=335$, weighted =301.12) and CFR ($n=26$).

Table 3: Event Type Distribution by Database

Event Type	CISSM (N=335)	CFR (N=26)
Disruptive	185.4 (61.6%)	N/A
Exploitive	93.5 (31.1%)	N/A
Mixed	15.7 (5.2%)	N/A
Undetermined	6.5 (2.2%)	N/A
Espionage	N/A	15.0 (57.7%)
Denial of service	N/A	4.0 (15.4%)
Sabotage	N/A	4.0 (15.4%)
Data destruction	N/A	3.0 (11.5%)
Total (weighted)	301.1	26.0
Total (records)	335	26

Taxonomies between CISSM and CFR are incommensurable; presented descriptively without statistical comparison. Weights (analysis_weight) applied for percentages; counts reflect total records per source.

conflict, that hacktivism is the dominant form of cyber operation in the Russia-Ukraine war, is at least in part a finding about the structure of cyber conflict data collection. This does not diminish the empirical significance of hacktivist activity; Rodenhäuser [20] demonstrates that civilian hackers raise consequential legal and normative questions under international humanitarian law. It does, however, require that scholars account for collection methodology as a confound before drawing substantive conclusions about actor prevalence from any single database.⁴³

5.3 Two-Layer Model (F3)

The preceding findings demonstrate that the three databases index systematically different event populations (F1, §5.1) and that cross-source variation in actor-type and attribution-rate distributions reflects collection methodology rather than a unitary empirical reality (F2, §5.2). These observations can be reconciled under a two-layer model that organizes the divergent database profiles into a single theoretical framework.

The model. We propose that cyber operations in the Russia-Ukraine war occupy two analytically distinct layers. The *surface layer* comprises hacktivist operations (DDoS attacks, website defacement, and information operations) that are publicly claimed on Telegram, observable in real time, and documented through open-source intelligence. The *subsurface layer* comprises state-sponsored operations (espionage, sabotage, and persistent-access campaigns) that are covert, deniable, and identified through government attribution or curated threat-intelligence. These layers interact: states may tacitly tolerate aligned hacktivist groups,[8, 20] but the two layers follow different strategic logics, with the surface layer expressive and reactive and the subsurface layer persistent and strategic.⁴⁴

Mapping layers to databases. Each database’s collection methodology determines which layer it predominantly captures, explaining the near-zero overlap documented in §5.1. CISSM’s OSINT pipeline (hacktivist Telegram channels, public self-attestation, threat-intelligence feeds) reliably captures surface-layer

⁴³Slayton [22] develops the general epistemological point: measurement choices determine which features of a phenomenon become visible. The two-layer model (§5.3) applies this logic to the specific case of cyber conflict databases.

⁴⁴Derbyshire et al. [8] periodize escalating hacktivism targeting operational technology; Katagiri [17] documents state-APT campaigns at a different tempo and visibility.

operations, producing a hacktivist-majority corpus (38.5% pro-Russian hacktivist) with high self-attribution (52.8%).^[14] CSIS’s state-curated methodology (official government attribution and authoritative reporting) predominantly captures subsurface-layer operations, yielding a state-majority corpus (76.5% Russian state) with low self-attribution (18.5%). CFR’s media-aggregated methodology samples both layers at the threshold of policy-relevant news coverage, producing the smallest corpus ($n = 26$, all state-actor) and the earliest temporal stop (December 2022).⁴⁵ Figure 3 illustrates this mapping conceptually.

Figure 3: Two-layer model of cyber operations in the Russia-Ukraine war. The surface layer (hacktivist DDoS, defacement; self-attributed, observable, captured by OSINT collection) maps to CISSM’s database profile. The subsurface layer (state APT, espionage, sabotage; covert, deniable, curator-identified) maps to CSIS and CFR profiles. Databases sample different layers, producing the cross-source divergence documented in §5.1 and §5.2.

Temporal evidence. The two-layer model predicts distinct temporal signatures for each layer. Surface-layer activity should be episodic and reactive, driven by events and Telegram call-to-action campaigns; subsurface-layer activity should be steady, reflecting persistent state intelligence operations. The temporal data support this distinction (Figure 1). CISSM’s monthly volume exhibits pronounced spikes during the first six months of the war and during subsequent hacktivist surges, consistent with surface-layer dynamics.⁴⁶ CSIS shows comparatively steady monthly counts (modal volume of two records per month, none exceeding six), consistent with persistent subsurface state operations. CFR’s early termination, with no records after

⁴⁵CFR contains no hacktivist records and 0% self-attribution; its event-type taxonomy (Espionage, Sabotage, Denial of Service) reflects subsurface-layer operations that attract policy attention.

⁴⁶Peak CISSM weighted monthly counts occur in April 2022 ($n = 18.3$), October 2022 ($n = 21.2$), and November 2022 ($n = 23.5$), coinciding with major pro-Russian hacktivist campaigns.

December 2022, reflects declining media attention as the conventional war protracted, rather than a cessation of subsurface activity.[4]

Theoretical anchoring. The two-layer model does not claim new empirical territory; it organizes existing observations into a framework that explains systematic disagreement among single-database studies. Gray’s (2024) finding that 61% of documented operations are hacktivist, which appears to conflict with Katagiri’s (2024) emphasis on state APTs, reflects an observation of different layers through different instruments rather than a genuine contradiction. Slayton’s (2017) measurement sensitivity thesis, that how researchers operationalize a construct determines what they observe, provides the epistemological foundation: the surface and subsurface layers emerge as distinct patterns only when multiple instruments are compared. Valeriano and Maness’s (2015) selection effects, whereby database inclusion criteria shape empirical distributions, find concrete expression in the two-layer structure. As Blagden [3] suggests, disagreement about cyber operations may be infrastructural rather than substantive. The two-layer model thus constitutes a methodological reconciliation: scholars who appear to disagree about cyber conflict are often observing the same phenomenon through instruments that differentially amplify one layer over the other. This is a proposition for organizing future multi-source research rather than a tested theory, and one that invites validation by studies designed to sample both layers simultaneously.

6 Discussion

The preceding findings establish three empirical regularities: the three databases index systematically different event populations with near-zero verified overlap (F1, §5.1); cross-source variation in attribution rates and actor-type distributions reflects collection methodology rather than a unitary conflict reality (F2, §5.2); and these divergent observations can be reconciled under a two-layer model that distinguishes surface hacktivist operations from subsurface state campaigns (F3, §5.3). This section discusses what these findings mean, why they matter for policy, theory, and methodology, the limitations bounding our claims, and the research agenda they open.

6.1 Implications for Empirical Cyber Research

The Core Implication The near-zero cross-source overlap (F1) reflects the databases’ distinct design intentions rather than a flaw in any of them. CISSM tracks OSINT-visible operations, CSIS monitors strategically significant state-attributed incidents, and CFR catalogues policy-relevant events, and their divergence follows directly from these different mandates.[22, 25] Zero verified matches across 487 possible pairs shows that these databases capture fundamentally different phenomena in the same time and space, and do not merely disagree on marginal cases. A scholar using CISSM describes the surface layer of hacktivist self-attestation; one using CSIS describes subsurface state-curated incidents; one using CFR describes operations crossing a media news-worthiness threshold. These are accounts of different objects that happen to share a temporal and geographic label, rather than competing accounts of the same object. The χ^2 result ($\chi^2 = 87.83$, Cramér’s $V = 0.33$, $p < 0.001$) formalizes this: the association between source and actor type is systematic, with a medium-to-large effect size that cannot be explained by random variation alone.

The self-attribution gradient (F2) makes this epistemological point operational by quantifying exactly how methodology shapes observation. The progression from 52.8% (CISSM) to 18.5% (CSIS) to 0% (CFR) tracks the methodological distance from OSINT self-attestation through state-curated attribution to media aggregation. Non-overlapping Wilson confidence intervals (CISSM [47.5%, 58.1%], CSIS [11.6%, 28.3%], CFR [0.0%, 12.9%]) establish that these rates are not statistically compatible with a single underlying self-attribution propensity.[1] As Slayton [22] argues, measurement choices determine which features of a phe-

nomenon become visible; the gradient here shows precisely how collection protocols produce divergent portraits. The implication for single-database studies is straightforward but consequential: observed empirical regularities carry an unstated scope condition. A finding that “hactivism dominates cyber conflict” is valid for the event population the researcher’s chosen database captures, but it remains incomplete, and the incompleteness follows a systematic pattern rather than a random one.⁴⁷

The two-layer model (F3, §5.3) offers a synthetic resolution. Rather than treating the divergent database profiles as contradictory empirical findings, the model organizes them as observations of distinct but coexisting operational layers. The surface layer (hactivist DDoS, defacement, self-attested) and the subsurface layer (state APT, espionage, covert) follow different strategic logics, expressive versus strategic, reactive versus persistent, and different collection instruments differentially amplify one layer over the other. This is a framework for reconciling observations that appear incommensurable when viewed through any single instrument, rather than a tested theory in its own right.

The Core Implication Each database produces a distinct empirical portrait. CISSM yields a conflict dominated by hactivist DDoS and defacement with high self-attestation (52.8%). CSIS yields a conflict dominated by state-actor operations (76.5%), most lacking perpetrator claims. CFR yields a state-driven conflict (84.6%) that appears to end in December 2022. None of the three portraits is false; each is valid for the layer it samples, yet none is complete, and any two appear contradictory without reference to collection methodology. A scholar who finds hactivism dominant is not disagreeing with one who finds state-actor dominance; each observes a different layer through a different instrument.

This has three prescriptive implications for the field. First, researchers should acknowledge their database’s collection methodology as a scope condition, reporting sampling frame, attribution source profile, and known coverage gaps as an integral part of their empirical contribution.^[6, 22] Second, where possible, researchers should triangulate across multiple sources before concluding about actor prevalence or tactical distributions.^[12, 25] Third, the field should treat empirical findings as collection-conditional until cross-validated across databases with different methodologies.⁴⁸

All three databases are well constructed for their respective purposes; the challenge lies in how the field has used them. Research has largely proceeded as though the databases measure the same thing, when in fact they measure complementary slices of a complex phenomenon.^[23, 28] Until multi-source collection protocols become standard practice, “findings” from single-database studies should be read as findings about what that database’s methodology reveals, rather than about the conflict itself. Gray ^[14] already demonstrates that restricting interpretation to one collection domain is methodologically sound; our contribution is to show that this restriction is structurally required, not merely a cautious option, given how data infrastructure shapes empirical knowledge.

Defending the Contribution A skeptical reader might object that these databases were designed to capture different things, so their outputs naturally differ, and ask what value quantification adds beyond that observation. The answer is that knowing *how much* incompleteness exists is categorically different from knowing that it exists. F1’s zero verified matches across 487 pairs and F2’s 52.8-percentage-point attribution gradient move us from vague acknowledgment of database bias to precise measurement of its magnitude and direction. The pattern of missingness is itself informative: if OSINT sources systematically over-represent publicly claimed operations while state-curated sources under-represent them, the gap constitutes signal about attribution incentives rather than noise.^[21, 23] This precision matters for policy, theory,

⁴⁷This mirrors King et al. ^[18]: inference quality depends on the match between data-generating process and research question. Here, each database has a different data-generating process.

⁴⁸Gray ^[14] provides the template: Gray restricts interpretation to the OSINT-collection domain. We extend this by showing that what appears to be a conflict characteristic is a methodological artifact visible only through cross-source comparison.

and methodology.

Policy. If 52.8% of CISSM records are self-attributed hacktivist while CFR records zero hacktivists, policy conclusions about “state-dominated” or “hacktivist-driven” cyber conflict may reflect database choice rather than conflict reality. Recommendations from any single database implicitly assume that its sampling frame corresponds to the universe of relevant operations, an assumption our findings invalidate. Different databases imply different threat distributions and therefore different policy priorities.[5, 27]

Theory. The two-layer model (F3) challenges the state-versus-nonstate dichotomy underpinning much IR theory on cyber conflict.[16, 19] Surface hacktivist and subsurface state operations follow distinct strategic logics, expressive versus covert, reactive versus persistent, which suggests that debates about “who is the primary actor” may ask the wrong question. The productive question is instead which layer a given instrument captures, and what inferences about the other layer it precludes.[8, 20, 22] This reframing moves the discussion from empirical adjudication to methodological alignment.

Methodology. Collection-driven measurement is a general problem that extends well beyond cyber conflict databases. Our analytical approach, comparative multi-source characterization with methodological signature analysis, is transferable. Terrorism databases (e.g., GTD vs. RAND), civil conflict datasets (e.g., UCDP/PRIO vs. ACLED), and human rights monitoring collections face the same fundamental challenge: different instruments produce systematically different empirical portraits of the same phenomenon. Our contribution is to demonstrate that quantifying the divergence, rather than selecting one database and proceeding as though it were a transparent window, produces a structured map of where and why instruments disagree. This is precisely what the field needs to understand the political economy of cyber conflict attribution, and no single database can provide it alone.

6.2 Limitations and Future Research

Several caveats bound our claims. First, the three-database ceiling reflects data availability rather than analytical choice. The Hacktivism Database, ACLED’s cyber module, and industry collections could not be integrated owing to incompatible access protocols, temporal windows, or conflict filters. Near-zero overlap may not extend to these unexamined sources.

Second, all three databases are observational. The cross-sectional design precludes causal claims about why collection methodology produces particular distributions. Systematic covariation between methodology and empirical profile is strongly suggestive of a measurement effect, but we cannot rule out that databases index genuinely different subsets of a broader phenomenon for reasons orthogonal to methodology.

Third, temporal asymmetry limits cross-source comparison. CFR terminates in December 2022 (10 months); CISSM covers 35 months, CSIS 34. CFR is a snapshot of the invasion’s first year, the period of highest hacktivist visibility and the phase most likely to attract media attention, and its actor-type and event-type profiles may not generalize to later stages of the conflict.

Fourth, all three databases primarily index English-language sources. CISSM includes some Russian- and Ukrainian-language Telegram channels, but coding frameworks, news sources, and curation reports are predominantly English. Non-English operations, especially in Russian, Ukrainian, or Mandarin, may be systematically underrepresented, and the non-English hacktivist ecosystem may be larger than the English-language record suggests.

Fifth, event-type taxonomies are incommensurable across databases (§3), limiting operational-modality analysis to descriptive comparison of CISSM and CFR. CSIS’s absence of structured event types is a notable gap.

Sixth, the single-conflict design constrains generalization. The Russia-Ukraine war is unusually data-rich [28], and database divergence may be larger or smaller in conflicts with different media attention, attribution incentives, and hacktivist mobilization patterns. The two-layer model may be specific to conflicts where a state-versus-nonstate distinction maps onto observable operational tempo differences, which may not hold in cyber operations short of armed conflict.

Future Research These limitations define a research agenda. First, the two-layer model should be tested in other conflict dyads, such as Israel-Palestine, US-China, and India-Pakistan, where multiple databases track cyber operations. If the model holds across contexts, it captures a structural feature of cyber operations; if not, the surface-subsurface distinction may be case-specific.

Second, systematic non-English source integration is essential. A pilot study comparing English- and Russian-language coverage of the same conflict period could quantify the direction and magnitude of language bias. Extending collection to Mandarin, Arabic, and Persian platforms would test whether observed actor-type distributions reflect language access rather than operational reality.

Third, the field needs standardized multi-source collection protocols, analogous to pre-registered search strategies in medical systematic reviews, specifying which databases are consulted, how coverage gaps are handled, and how collection-method sensitivity is reported.

Fourth, the enrichment pipeline produced approximately 350 URL contexts suitable for qualitative validation. OCR and content analysis of these source URLs would allow independent verification of attribution claims and would ground the attribution-method coding in observable evidence, a valuable complement to the quantitative analysis presented here.

Fifth, a “collection sensitivity index,” a quantitative summary measuring how estimates shift when analyst choices about source inclusion, temporal window, or actor-type classification vary, would help researchers calibrate confidence in single-database findings. Bootstrapping alternative database-weighting schemes from our data could produce a prototype.

None of these extensions requires abandoning single-database research. What they require is treating database choice as a methodological variable, on par with measurement selection, case selection, and model specification, rather than as a transparent window onto cyber conflict. The present study demonstrates that the window is not transparent. The question is whether the field will treat this as a limitation to manage or as a feature of the data infrastructure to exploit for more rigorous empirical research.

7 Conclusion

This study set out to determine whether single-database analyses of cyber conflict produce systematically incomplete pictures. The answer is yes: three independently constructed databases indexing the same conflict over the same period record near-zero verified overlap, fundamentally different actor-type compositions, and a self-attribution gradient that tracks collection methodology rather than perpetrator behaviour. Specifically, (a) zero of 487 cross-source pairs yielded a verified incident-identity match, with a strong association between source and actor type ($\chi^2 = 87.83$, Cramér’s $V = 0.33$); (b) self-attribution rates follow a perfect methodological gradient, 52.8% in the OSINT database (CISSM), 18.5% in the state-curated database (CSIS), and 0% in the media-aggregated database (CFR), with non-overlapping confidence intervals; and (c) these divergent observations are reconciled by a two-layer model distinguishing surface hacktivist operations from subsurface state campaigns. What scholars observe about cyber conflict depends substantially on which database they use: single-database studies carry unstated scope conditions that limit the generalisability of their empirical claims.

The study makes two contributions. Methodologically, we provide the first systematic multi-source quantification of collection-driven measurement in cyber conflict research, demonstrating that the effect

is large enough to invert substantive conclusions. The 52.8 percentage-point gap in self-attribution between CISSM and CFR, the inversion of actor-type profiles across databases from hacktivist-majority to state-dominant, and the 0/487 verified overlap constitute a structural challenge to the evidentiary basis of single-database empirical claims, not a subtle correction to existing findings. Analytically, the two-layer model provides a synthetic framework that organises the divergent database profiles into a coherent picture, connecting existing findings, hacktivist operational dominance in OSINT data,[14] state APT emphasis in strategic studies,[17] and political constraints on attribution[5, 15], into a single infrastructural explanation for why databases disagree.

Several limitations constrain the interpretation of these results.⁴⁹ The analysis covers three databases and one conflict; the observational design precludes causal claims about why databases diverge. CISSM constitutes 75.8% of the analysis corpus, and the CSIS event-type gap restricts one analytical dimension to descriptive comparison. These limitations reflect the data infrastructure this study characterises rather than design weaknesses: the specific numbers, the 52.8% CISSM self-attribution rate, the 0/487 overlap, and the $V = 0.33$ effect size, describe this particular comparison and should not be mistaken for universal parameters of cyber conflict.

Future research should extend this multi-source approach in three directions. First, the two-layer model should be tested on other conflict dyads, such as Israel-Palestine, US-China, and India-Pakistan, to determine whether the surface-subsurface distinction generalises beyond the Russia-Ukraine case. Second, non-English-language sources should be integrated to assess whether the OSINT capture of self-attestation reflects Anglophone-media bias rather than a general property of cyber conflict documentation. Third, the field requires multi-source collection protocols that deliberately sample both layers within a unified framework, rather than relying on post-hoc comparison of independently constructed databases. Until such protocols are developed, the empirical study of cyber conflict will remain, at least in part, a study of the databases that make it possible.
